ABSTRACT

Key-words:

$\delta^{15}\text{N}$, fish community, anthropogenic activity, watershed, buffer zone, lakes

The relationships between fish community $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values and land use in watersheds and in buffer zones of nine French lakes were studied. The results showed inter-lakes variability of mean $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values for different fish species. The study of correlations between fish $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values and the proportions from different land use categories in watersheds showed a land use effect on fish $\delta^{15}\text{N}$ values but not on $\delta^{13}\text{C}$ values. The results underlined the great impact of manure spreading on grasslands as a nitrate source in our lakes. Nevertheless, the best correlations between fish $\delta^{15}\text{N}$ values and land use were obtained when the entire fish community (*i.e.* the whole fish community mean $\delta^{15}\text{N}$ values in each lake) and all anthropogenic activities (residential lands, camp sites and grasslands for our systems) were considered in either watersheds or in buffer zones. Thus, for our sites, the fish $\delta^{15}\text{N}$ values are useful to evaluate nitrogen inputs from human and animal wastes at the watershed-scale as well as at the buffer zone-scale. The absence of land use effect on the fish community $\delta^{13}\text{C}$ values could be at least partly explained by the small size of these lakes in which it has been shown that consumers, namely macroinvertebrates, have $\delta^{13}\text{C}$ values largely influenced by organic matter recycling activity.

RÉSUMÉ

Influence des activités humaines des bassins versants sur les ratios d'isotopes stables d'azote et de carbone des poissons dans neuf lacs français

Mots-clés :

$\delta^{15}\text{N}$, communautés piscicoles, activités humaines, bassin versant, zones tampon, lacs

Les relations entre les valeurs de $\delta^{15}\text{N}$ et $\delta^{13}\text{C}$ des communautés pisciaires, l'occupation des bassins versants et des zones tampon de neuf lacs français ont été étudiées. Les résultats montrent une variabilité inter-lac des valeurs moyennes de $\delta^{15}\text{N}$ et $\delta^{13}\text{C}$ pour les différentes espèces. L'étude des relations entre les valeurs isotopiques des poissons et les proportions des différentes catégories d'usage des bassins versants montre une corrélation entre l'occupation des sols et les valeurs de $\delta^{15}\text{N}$ des poissons alors qu'aucune corrélation n'apparaît si l'on considère les valeurs de $\delta^{13}\text{C}$. Les résultats obtenus mettent en évidence l'impact important

de l'utilisation des lisiers sur prairies comme source de nitrate dans ces lacs. Les meilleures corrélations entre les valeurs de $\delta^{15}\text{N}$ des poissons et l'occupation de l'espace sont obtenues quand la communauté de poissons dans son ensemble (c'est-à-dire les valeurs moyennes de $\delta^{15}\text{N}$ pour toutes les espèces dans chaque lac) et toutes les activités anthropiques (zones d'habitation, camping et prairies) sont prises en compte aussi bien au niveau du bassin versant que de la zone tampon. Pour les lacs étudiés, les valeurs de $\delta^{15}\text{N}$ des poissons permettent d'évaluer l'impact des apports d'azote dus aux déchets humains et animaux, aussi bien au niveau du bassin versant que de la zone tampon. L'absence de corrélation entre l'occupation des sols et les signatures en carbone des poissons peut être expliquée, au moins partiellement, par la petite taille de ces lacs dans lesquels il a été montré que les consommateurs, dont les macroinvertébrés, ont des valeurs de $\delta^{13}\text{C}$ largement influencées par le recyclage interne de la matière organique.

INTRODUCTION

For the last twenty-five years, stable isotope analysis has been used to study food webs and energy flows in both terrestrial and aquatic ecosystems (Gu *et al.*, 1997; Ponsard and Ardit, 2000; Ehleringer *et al.*, 2002). Among the stable isotopes, stable nitrogen isotope ratios ($\delta^{15}\text{N}$) are useful for defining the structure of the food web and, especially the trophic position of consumers (Vander Zanden *et al.*, 1997; Post *et al.*, 2000) whereas stable carbon isotopes are used to track the carbon source from its origin at the base of the food web (Schlinder *et al.*, 1997; Post *et al.*, 2000). In fact, $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values are passed on from the food source to consumers with characteristic enrichment. $\delta^{13}\text{C}$ changes little from prey to predator with mean trophic fractionation of $+0.39\text{‰} \pm 1.3$ in aquatic food webs (Post, 2002). In case of $\delta^{15}\text{N}$, consumers are enriched compared to the food, with a typical fractionation of $+3.4\text{‰} \pm 1.1$ in aquatic food webs (Post, 2002). Therefore, isotope signatures of primary and secondary consumers scale to isotopic signatures of primary producers (Lajtha and Marshall, 1994). Variation in primary producer isotope ratios is integrated in higher level consumers.

The available dissolved nitrogen sources (DIN) for primary producers are varied (atmospheric source, ammonium, NO_3^-) and, different processes may be involved in establishing the $\delta^{15}\text{N}$ values of DIN: microbial nitrification, denitrification and anthropogenic contributions (Cabana and Rasmussen, 1996; Cole *et al.*, 2004). Concerning this last point, several groundwater studies have used stable isotope signatures of naturally abundant NO_3^- to identify the major N sources (wastewater, fertilizer, and atmospheric deposition) to aquifers (Kreitler *et al.*, 1978; Kreitler, 1979; Aravena *et al.*, 1993). These studies have shown that groundwater influenced only by atmospheric deposition have $\delta^{15}\text{N}$ values for NO_3^- ranging from +2 to +8‰, whereas NO_3^- derived from human and animal wastes is more enriched in ^{15}N (+10 to +20‰) and nitrate from synthetic fertilizers is more depleted in ^{15}N (-3 to +3‰) (Gormly and Spalding, 1979; Macko and Ostrom, 1994). Thus, N contribution from different sources can produce some variation in the $\delta^{15}\text{N}$ signature of primary producers at the base of the food chain ($\delta^{15}\text{N}$ baseline) which is passed on to the consumer species. Cabana and Rasmussen (1996), McClelland *et al.* (1997), Lake *et al.* (2001) and Cole *et al.* (2004) have emphasized the influence of anthropogenic activities (wastewater in particular) in watersheds or in buffer zones on the $\delta^{15}\text{N}$ values of primary producers and consumers in estuarine and in small freshwater systems.

About $\delta^{13}\text{C}$ values, among factors that could affect autochthonous primary producers $\delta^{13}\text{C}$ ($\delta^{13}\text{C}$ baseline), and consequently consumers $\delta^{13}\text{C}$, the major one is the dissolved inorganic carbon (DIC) $\delta^{13}\text{C}$ value. This latter depends on its origin: dissolved atmospheric CO_2 ($\delta^{13}\text{C} = 0\text{‰}$, Peterson and Fry, 1987), dissolved carbon from the substratum and dissolved CO_2 from respiration as a result of organic matter mineralization. It has been shown that heterotrophic organic matter recycling activity may lead to a decrease in DIC $\delta^{13}\text{C}$ values (France, 2000) whereas an increase in lake primary production may lead, in great lakes,

to an increase in DIC $\delta^{13}\text{C}$ values and consecutively in that of the whole lake food web (Gu *et al.*, 1996; Schindler *et al.*, 1997). The proportion of carbon derived from the dissolution of atmospheric CO_2 and from respired CO_2 depends on the lake area and the nutrient inputs (Schindler and Scheuerell, 2002). Therefore, nutrient inputs from the watershed or the buffer zone may modify DIC $\delta^{13}\text{C}$ values and consecutively $\delta^{13}\text{C}$ baseline values. In addition, benthic and pelagic primary producers discriminate differently against ^{13}C so that, with the same dissolved atmospheric carbon source, the benthic producers show highest $\delta^{13}\text{C}$ values (-27‰, Sierszen *et al.*, 2003) than the pelagic one (-31‰, Sierszen *et al.*, op.cit.).

Fish nitrogen and carbon isotopic ratios may then reflect change in $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ baselines following variations in DIC and DIN isotopic ratios, or change in fish diet e.g. trophic shift from a benthic to a pelagic food source following change in nutrient inputs (Vadeboncœur *et al.*, 2001).

The first aim of this study was to test the relationships between $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values of fish and the land use in watersheds and in buffer zones, in nine French lakes. Secondly, the aim was to define, among studied systems, the major anthropogenic activity that influences fish $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values. In fact, anthropogenic nutrient inputs changed nitrogen and carbon availability and cycling, which are likely to increase ecosystem productivity, shift the balance between benthic and pelagic productivity, modify the food chain length, increase the carrying capacity of the system for fishes and influence the $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ fish values.

METHODS

> STUDY SITES

Nine French lakes located in the Jura region of eastern France were studied: lakes Bonlieu, Chalain, Clairvaux, Ilay, Maclu, Narlay, Remoray, Les Rousses and Saint-Point. Their morphological characteristics greatly differed as well as their altitude but, their watersheds shared the same calcareous geological substratum (Table I).

> FISH SAMPLING

Fish were collected, from 2002 to 2005, with gillnets of varying mesh (25 mm to 60 mm knot to knot), set in benthic and pelagic zones in order to sample all species. Only adults of each species were selected for stable isotope analysis. A minimum of three fishes per species were selected for stable isotope analysis. For some sites (lakes Bonlieu, Ilay and Maclu), only one individual for one fish species was available and its $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values were used (*i.e.* pike *Esox lucius* L. or/and tench *Tinca tinca* L.). For the other sites and species, the each fish species mean $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values for each lake were considered and, the mean of these means was considered to define the whole fish community mean $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values.

> CARBON AND NITROGEN STABLE ISOTOPE RATIOS

One milligram samples of dried and finely ground dorsal muscle of each organism were weighted in 6 x 4 mm tin cups for CF-IRMS analysis using a Europa Scientific ANCA-NT 20-20 Stable Isotope Analyser with a NCA-NT Solid/Liquid Preparation Module (PDZ Europe Ltd., Crewe, UK). The analytical precision (SD), estimated from five standards analysed along with the samples, was 0.2‰. Working standards for analytical precision consisted of 1.0 or 1.5 mg leucine prepared by freeze drying 50 mL of a 20 mg·mL⁻¹ stock solution in the tin cups, and calibrated against "Europa flour" and IAEA standards N1 and N2. All stable isotope values are expressed in the δ notation, in units of parts per thousand (‰) where: $\delta = [(R_{\text{sample}} - R_{\text{standard}}) / R_{\text{standard}}] \times 1000$. For $\delta^{15}\text{N}$ values, $R = ^{15}\text{N}/^{14}\text{N}$ and atmospheric nitrogen is standard material and for $\delta^{13}\text{C}$ values, $R = ^{13}\text{C}/^{12}\text{C}$ and standard material is Pee Dee Belemnite.

> WATERSHED DESCRIPTION

In each watershed, the different categories of land use (water, grassland, residential land, camp sites, forest and peat bog) were charted from NGI (National Geographical Institute) 1/25 000 maps and modified by visit of the sites. Agricultural practices were examined. The area of each land use category was calculated and converted as a percentage of the total area of each watershed. The watersheds of the nine studied lakes are rural and the agricultural practice was dairy production. This practice was accompanied by substantial manure spreading on grassland. Three land use categories can form potential inputs of human and livestock waste nitrogen (grassland, residential land, camp sites) so that they were pooled together to evaluate the global anthropogenic activity.

Furthermore, buffer zones surrounding each lake, defined as a ground strip of $150 \text{ m} \pm 50$ according to topography, were studied: as for the watershed, the different categories of land use were charted from NGI maps then field work. Their area were calculated, then these latter were converted as a percentage of the total area of each buffer zone. The global anthropogenic activity was evaluated by pooling even categories as for watersheds.

> STATISTICAL ANALYSIS

$\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values were modelled according to the General Linear Model (GLM) as a linear function of fish species and land use variables of the form: $y = a_1 + bx_2 + cx_3 + dx_4 + ex_5 + fx_6 + gx_7 + \varepsilon$ where y is the response variable ($\delta^{15}\text{N}$ or $\delta^{13}\text{C}$), x_1 is a factor (each level being fish species), x_2 grassland area, x_3 residential land, x_4 forest area, x_5 water area, x_6 camp sites, x_7 peat bog area and ε the residuals. A random effect was added to account for non independence of each measure at each lake. Residuals were examined and outliers and variance heteroscedasticity checked. Under the null hypothesis (H_0) of each model parameters equal to zero, the significance of parameters was then checked by analysis of variance (H_0 was rejected at a 0.05 probability). Non significant variables were thus removed sequentially in order to obtain a final model. A fish size effect was also added in the $\delta^{15}\text{N}$ final model but no significant size effect has been observed (ANOVA, $DF = 352$, $P = 0.14$).

Several kinds of models were examined changing the way land use variables were expressed. On the whole watershed, and on the buffer zone, land use variables were expressed (1) in hectares in order to take the size of watersheds or buffer zones into account, (2) in percentage in order to take the proportion of each land use component into account independently of watershed or buffer zone sizes.

Computing and graphical displays were performed using R 2.4.1 and the package nlme (R Development Core Team, 2006).

RESULTS

Six species of fish were caught. Species mean $\delta^{15}\text{N}$ values ranged from 3.6‰ for roach in Lake Bonlieu to 13.2‰ for pike in Lake Chalain and $\delta^{13}\text{C}$ values ranged from -36.7‰ in Lake Remoray for whitefish to -27.6‰ for rudd in Lake Bonlieu (Table II, Figures 1 and 2). The largest range for species mean $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values in one lake is in Lake Chalain with a range from 8.0‰ for rudd to 13.2‰ for pike for $\delta^{15}\text{N}$ and a range from -26.6‰ for rudd to -35.9‰ for whitefish for $\delta^{13}\text{C}$.

The fish $\delta^{15}\text{N}$ values were statistically different among species for each lake (Kruskal-Wallis, $n > 36$, $P < 0.0358$) except for Lake Les Rousses (Kruskal-Wallis, $n = 21$, $P = 0.0943$). Perch and/or whitefish $\delta^{15}\text{N}$ could be statistically separated from the other species (Scheffer's test) and pike was the most ^{15}N enriched species except for Lake Saint-Point.

About fish $\delta^{13}\text{C}$ values, statistical differences among species for each lake were also observed (Kruskal-Wallis, $n = 21$, $P < 0.0041$). Except for Lake Bonlieu, whitefish $\delta^{13}\text{C}$ was lower than roach and/or rudd $\delta^{13}\text{C}$ values (Scheffer's test).

Figure 2
Box-plot of $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ fish values in the nine French lakes.

Figure 2
Graphe box-plot des valeurs de $\delta^{15}\text{N}$ et $\delta^{13}\text{C}$ des poissons dans neuf lacs français.

When species of each lake were ordered in increasing mean isotope values, it appears that the species positions greatly differed between lakes. Whitefish had the most variable position both for carbon and nitrogen but its mean $\delta^{13}\text{C}$ value was the lowest compared to that of the other species. The overlaps between the ranges for species mean $\delta^{13}\text{C}$ values were less than for $\delta^{15}\text{N}$ values (Fig. 2). Rudd and roach presented large ranges for both carbon and nitrogen ratios.

> LAND USE IN WATERSHEDS AND IN BUFFER ZONES

Considering their watershed land use, the lakes can be classified based on an increasing order of percentage of land affected by anthropogenic activity as followed: Bonlieu, Maclu, Ilay, Clairvaux, Narlay, Chalain, Saint-Point, Remoray and Les Rousses with 47.18% of land affected by anthropogenic activity (Table I).

The same classification was obtained when the percentage of the buffer zones affected by anthropogenic activity was considered, except for Lake Saint-Point. This lake had the buffer zone most affected by anthropogenic activity while its watershed was less affected than those of lakes Remoray and Les Rousses (44.40%, 45.26% and 47.18% of land affected by anthropogenic activities respectively). For lakes Bonlieu and Maclu, the buffer zones were not affected by anthropogenic activity; land use consisted of wetland and forest cover.

> RELATIONSHIPS BETWEEN LAND USE IN WATERSHEDS AND IN BUFFER ZONES AND FISH $\delta^{15}\text{N}$ AND $\delta^{13}\text{C}$ VALUES

The study of relationships between fish $\delta^{15}\text{N}$ or $\delta^{13}\text{C}$ values and both fish species and area of land use categories in watershed expressed in hectares showed a fish species effect on the various $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values (ANOVA, $n = 417$; for $\delta^{15}\text{N}$ values, $DF = 403$, $P < 0.0001$; for $\delta^{13}\text{C}$ values, $DF = 335$, $P < 0.0001$) but no effect of watershed size (ANOVA, $n = 417$; for $\delta^{15}\text{N}$ values, $DF = 3$, $P = 0.3601$; for $\delta^{13}\text{C}$ values, $DF = 3$, $P = 0.1667$). Pike was the most ^{15}N enriched species in the studied lakes. About $\delta^{13}\text{C}$ values, whitefish was the least ^{13}C enriched whereas the highest $\delta^{13}\text{C}$ values were observed for rudd. When the proportion of land use categories was considered and expressed in percentage to exempt from watershed size, there were a fish species effect and also a land use effect on fish $\delta^{15}\text{N}$ values (Table III). Factors affecting most the fish $\delta^{15}\text{N}$ values were the grassland area proportion then

Table III

Analysis of variance on the parameters of model: $\delta^{15}\text{N}$ values function of fish species and land use variables in watersheds and buffer zones: $y = ax_1 + bx_2 + cx_3 + dx_4 + ex_5 + fx_6 + gx_7 + \varepsilon$ where y is the response variable ($\delta^{15}\text{N}$ values), x_1 is a factor (each level being fish species), x_2 % grassland area, x_3 % residential land, x_4 % forest area, x_5 % water area, x_6 % camp sites, x_7 % peat bog area and ε the residuals.

Tableau III

Analyse de variance sur les paramètres du modèle : valeurs de $\delta^{15}\text{N}$ en fonction de l'espèce de poisson et des variables d'usage des sols dans les bassins versants et les zones tampon : $y = ax_1 + bx_2 + cx_3 + dx_4 + ex_5 + fx_6 + gx_7 + \varepsilon$ où y est la variable réponse (valeurs de $\delta^{15}\text{N}$), x_1 est un facteur espèce (chaque niveau étant une espèce de poisson), x_2 % de surface en prairies, x_3 % de zones résidentielles, x_4 % de forêts, x_5 % de surface en eaux, x_6 % de campings, x_7 % de tourbières et ε un résidu.

	Watershed scale			Buffer zone scale		
	Degrees of freedom	F-values	P-values	Degrees of freedom	F-values	P-values
Fish species	403	3492.105	< 0.0001	403	351.7791	< 0.0001
Grassland	4	620.289	< 0.0001	5	11.2697	0.0202
Forest				5	1.0073	0.3616
Residential land	4	149.372	0.0003			
Water area	4	3.935	0.1183			
Camp sites	4	16.908	0.00147	5	43.3497	0.0012
Peat bog	4	1.288	0.8252	5	5.7563	0.0617

the residential land and the camp sites proportions in watershed (Figure 3a). Pooled as anthropogenic activities, the sum of these three parameters is well correlated with the fish community $\delta^{15}\text{N}$ values (Figure 4). On fish $\delta^{13}\text{C}$ values, this land use effect wasn't observed (ANOVA, $n = 417$, $DF = 4$, $P = 0.1623$).

For the buffer zone, the same effects were obtained, namely:

– When the area of land use categories was expressed in hectares, a fish species effect on the various $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values was emphasized (ANOVA, $n = 417$; for $\delta^{15}\text{N}$ values, $DF = 403$, $P < 0.0001$; for $\delta^{13}\text{C}$ values, $DF = 403$, $P < 0.0001$) but no effect of buffer zone size was observed (ANOVA, $n = 417$; for $\delta^{15}\text{N}$ values, $DF = 4$, $P = 0.0852$; for $\delta^{13}\text{C}$ values, $DF = 4$, $P = 0.3053$).

– When the land use categories were expressed in percentage, there were a fish species effect and a land use effect on fish $\delta^{15}\text{N}$ values (Table III) but only a fish species effect on fish $\delta^{13}\text{C}$ values (ANOVA, $n = 417$, $DF = 403$, $P < 0.0001$). However, in this case, the variables affecting most the fish $\delta^{15}\text{N}$ values were respectively the camp sites proportion then the grassland area proportion with little difference; the residential land proportion not variable enough wasn't included in the model (Figure 3b). As seen for watershed land use, the buffer zone proportion affected by anthropogenic activities is well correlated with the fish community $\delta^{15}\text{N}$ values ($y = 0.098x + 6.91$, $R^2 = 0.9$).

DISCUSSION

Many studies have used stable nitrogen and carbon isotope ratios to represent the trophic structure of aquatic systems and to indicate the trophic position of aquatic consumers (Peterson and Fry, 1987; Cabana and Rasmussen, 1994). The $\delta^{15}\text{N}$ value of a consumer depends on two main factors. It reflects first the lake $\delta^{15}\text{N}$ baseline value ($\delta^{15}\text{N}$ of the primary

Relations entre les valeurs moyennes $\delta^{15}\text{N}$ des communautés de poissons et les proportions des bassins versants impactées par les activités humaines dans neuf lacs français (Bo : Bonlieu, Ch : Chalain, Cl : Clairvaux, Il : Ilay, Ma : Maclu, Na : Narlay, Re : Remoray, Ro : Les Rousses et Sp : Saint-Point).

producers) which is influenced by the DIN $\delta^{15}\text{N}$ value and the preferential form of the assimilated inorganic nitrogen source, NO_3^- ($\delta^{15}\text{N} < 10\text{‰}$) or NH_4^+ ($\delta^{15}\text{N} 20\text{--}30\text{‰}$) (Syväranta *et al.*, 2008). The $\delta^{15}\text{N}$ of a consumer also depends on its trophic level with an enrichment in ^{15}N equal to $3.4\text{‰} \pm 1.1$ for each trophic level (Post, 2002). The GLM showed both a fish species effect and a land use effect on the fish $\delta^{15}\text{N}$ values. The fish species effect could be explained by different trophic positions of the different species. Pike, which is a great predator in lakes (*i.e.* with a high trophic level), had the highest $\delta^{15}\text{N}$ values of all species except in lake Saint-Point. The comparison, between lakes, of the fish species position according to their mean $\delta^{15}\text{N}$ values underlined particular positions for various fish species in each lake. Concerning the land use effect the GLM showed that each category of anthropogenic activities occurring in the watershed and the buffer zone of our lakes significantly increased fish $\delta^{15}\text{N}$ values (Figures 3a and 3b). Two processes could be involved to explain the fish ^{15}N enrichment with the increase of anthropogenic activities. First these activities led to increasing nutrient inputs in lakes with increasing primary production, hypolimnion anoxic conditions and NH_4^+ production as results. After each overturn, ammonium primary assimilation in epilimnion could then lead to an increase in $\delta^{15}\text{N}$ of the whole lake food web including zooplankton (Syväranta *et al.*, 2008) and fish which are long term integrators of temporal isotopic variation in $\delta^{15}\text{N}$ baseline. Because among the studied lakes, Lake Saint-Point and Lake Les Rousses showed both elevated oxygen saturation in deep zone (minimal values equal to 15% saturation and 88% saturation respectively, non published data), and the highest fish $\delta^{15}\text{N}$ values, an increase of NH_4^+ assimilation did not seemed to be the major process implicated in the studied lakes. The second hypothesis is that all anthropogenic activities, in the studied watersheds and buffer zones, including agriculture which practice was accompanied by substantial manure spreading, led to human and livestock wastes inputs which have ^{15}N enriched nitrate (Macko and Ostrom, 1994). In the studied lakes, the fish community $\delta^{15}\text{N}$ values variability would then reflect differences in DIN $\delta^{15}\text{N}$ values due to different inputs of ^{15}N enriched nitrate. Among the three land use categories that constitute potential sources of nitrogen for the studied lakes, grassland seemed to be the major one at the watershed scale (Figure 3a) whereas at the buffer zone scale, camp sites and grassland have similar effects on $\delta^{15}\text{N}$ fish values (Figure 3b) suggesting their similar contributions to lake nitrogen inputs. Contrary to some previous studies in which agricultural activities were reported to be negatively correlated to consumer $\delta^{15}\text{N}$ values (McKinney *et al.*, 1999) our results showed that both urban and agricultural activities led to an increase of the consumer $\delta^{15}\text{N}$ values. In these previous studies agricultural practices implied the use of synthetic fertilizers with low $\delta^{15}\text{N}$ values whereas in the watersheds we have studied only farmyard manure were used with high $\delta^{15}\text{N}$ values. Other studies have also demonstrated that an increase in lake nutrients inputs, whatever the form, led to an increase in consumer $\delta^{15}\text{N}$ values (Vander Zanden *et al.*, 2005) following an enhancement of the denitrification process.

Our results are in agreement with those of Cabana and Rasmussen (1996) who linked elevated $\delta^{15}\text{N}$ values in primary consumers to increases in human population and to presumptive increases in wastewater inputs in the surrounding watersheds. They also agree with results from studies that demonstrated that $\delta^{15}\text{N}$ values of organisms (plants and animals) are useful indicators, as generalized measures, of incipient eutrophication in estuarine (McClelland *et al.*, 1997; McClelland and Valiela, 1998; Cole *et al.*, 2004) and lakes (Vander Zanden *et al.*, op.cit.)

Concerning the fish $\delta^{13}\text{C}$ values, the GLM showed a species effect but no land use effect. Because in the studied lakes, the correlation between fish $\delta^{15}\text{N}$ values and the global anthropogenic activity demonstrate that increasing anthropogenic pressure led to increasing lake nutrients or nitrogen inputs, one would be able to expect an increase in fish $\delta^{13}\text{C}$ values with increasing anthropogenic activity in watersheds and buffer zones. In fact, it has been shown that, in great lakes, enhancement of primary production led to an increase in consumer $\delta^{13}\text{C}$ values due to an increase of the dissolved atmospheric carbon in lake DIC (Perga and Gerdeaux, 2004). The same authors have also demonstrated that in small lakes, much more influenced by allochthonous organic matter inputs than great lakes, no correlation

appeared between whitefish $\delta^{13}\text{C}$ values and the lake trophic levels because respired DIC from allochthonous organic matter mineralization could supply the increase of carbon request instead of atmospheric carbon dissolution. In the present study, all lakes are small size lakes in which it has been shown that consumers, namely macroinvertebrates, have $\delta^{13}\text{C}$ values largely influenced by organic matter recycling activity (Borderelle *et al.*, 2008). In these lakes no correlation appeared between consumer $\delta^{13}\text{C}$ values and anthropogenic activity because the organic matter that sustain the microbial activity could be allochthonous or autochthonous or both with different proportions between lakes.

The fish species effect on the fish $\delta^{13}\text{C}$ values reflects the assimilation of different carbon sources. Whitefish with the lowest $\delta^{13}\text{C}$ mean value feeds preferentially on pelagic zone a phytoplankton source of carbon whereas the other species are more benthic consumers. It is now well known that, with the same source of DIC phytoplankton has a lower fractionation than benthic primary producers (France, 1995; Gu *et al.*, 1997; Sierszen *et al.*, 2004).

The between lake variability of fish species positions according to their $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values could be due to the flexible and opportunistic feeding habits of many fish species (Vander Zanden *et al.*, 1997) allowing a great variability of the fish species responses facing increasing nitrogen inputs (Table II). Roach and rudd present large ranges of values for both nitrogen and carbon (Figure 2). They are the most omnivorous of the fish species collected in our systems, taking up all the trophic niches according to the availability of feeding sources and being capable of consuming algae which proliferate when nutrients are in excess. Similarly, when watershed or buffer zone ^{15}N enriched nitrate comes in a system, many plants and periphyton can proliferate. They have elevated $\delta^{15}\text{N}$ values and can be consumed by roach. This could explain the largest ranges of carbon and nitrogen ratios for these species. However, the General Linear Model results encourage considering the whole fish community in each lake, *i.e.* the whole fish community mean $\delta^{15}\text{N}$ values, as an indicator of land use.

The anthropogenic activities, as the sum of the camp sites, the grassland and the residential land proportions in the watersheds and in the buffer zones, are then well correlated with the fish community $\delta^{15}\text{N}$ values. Thus, the fish $\delta^{15}\text{N}$ values were useful to evaluate human and livestock wastes nitrogen inputs at both watershed-scale as well as at buffer zone-scale. Contrary to results of Lake *et al.* (2001), for our sites, the land use in the entire watershed had the same importance as in the buffer zones and, the watershed-scale data of land use were as useful as the land use data in buffer zones for predicting increases in $\delta^{15}\text{N}$ values for each site.

In summary, these results support the use of fish $\delta^{15}\text{N}$ values as indicators of anthropogenic activities in watersheds and in buffer zones and underline the impact of nitrogen inputs when they are principally made by human and livestock wastes in lakes.
